Abstract

Cold tube drawing is a metal forming process which allows manufacturers to produce high precision tubes. The dimensions of the tube are reduced by pulling it through a conical converging die with or without inner tool. In this study, finite element modelling has been used to give a better understanding of the process.

This paper presents a model which predicts the final dimensions of the tube with very high accuracy. It is validated thanks to experimental tests. Moreover, five studies are performed with this model, such as the influence of the die angle on the drawing force or the influence of the relative thickness on the tube deformation.

Keywords: Precision metal forming, Cold tube drawing, Tube sinking, Mandrel drawing, Finite element method, Large deformation

1. Introduction

Medical devices, like stents, cardiac valves and implants, are manufactured with thin-walled tubes of small diameters [1]. As applications in the biomedical field, these tubes

Email addresses: florian.boutenel@mines-albi.fr (Florian Boutenel),
m.delhomme@minitubes.com (Myriam Delhomme), vincent.velay@mines-albi.fr (Vincent Velay),
r.boman@ulg.ac.be (Romain Boman)

require a very high precision in dimensions and surface finish. Also, these properties are
5 strongly linked to the quality of the metal forming process.

Cold tube drawing enables manufacturers to produce tubes with controlled dimensions,
good surface finish and high mechanical properties [2]. This metal forming process gives
a better tube quality compared to hot forming. Tube drawing consists in reducing tube
dimensions by pulling it through a conical converging die with or without inner tool.
10 Different drawing methods exist [3]. In this paper, two techniques are studied : tube
sinking and mandrel drawing (Figure 1).

FIGURE 1: Sketch of the two drawing methods studied in this paper (adapted from [4])

For both of them, the die calibrates the tube outer diameter. Tube sinking is the only
method which does not use an inner tool. The inner diameter is reduced because of the
free deformation inside the tube. In consequence, the inner surface finish is degraded. In
15 mandrel drawing, the inner tool, named mandrel, moves with the tube and calibrates its
inner diameter. The main drawback of this technique is related to the end of the drawing
operation where the tube is clamped around the mandrel. Thus, a reeling operation is
required to remove the tool.

20 The metal forming industry wants to perpetually improve productivity and product
quality. In order to reach this purpose, a better understanding of the processes is necessary.
On the one hand, a large series of experimental tests can be done. However, this type of
approach may be time and money consuming. On the other hand, lots of tests can be
performed virtually thanks to finite element (FE) modelling. It also gives access to physical
values, such as stresses and strains, which are not measurable during the process. Thus,
25 FE modelling seems to be a helpful tool.

Analytical solutions have been developed by several authors to study the effects of
process parameters. Um *et al.* [5] obtained an upper bound solution of fixed plug drawing
that can be simplified in the case of tube sinking. This method has been adapted to
mandrel drawing by Alexandrova [6] in the case of mandrel drawing. Later, the Hill's
30 general method of analysis for metalworking processes and a fracture criterion have been
added to this analytical model to study the workability of mandrel drawing [7]. Zhao *et al.* [8]
have proposed an analytical solution for tube sinking using an integration method
of strain rate vector inner-product.

Numerical studies of tube drawing using FE can also be found in the literature. A
35 finite element analysis has been conducted by Sawamiphakdi *et al.* [9] to determine the
initial tube sizes that give the appropriate mechanical properties after drawing. Linardon
et al. [10] combined a conical mandrel tube drawing test with a FE modelling to select
a failure criterion. The potential making of high-quality thin tubes with shape-memory-
alloy thanks to mandrel drawing has been studied by Yoshida *et al.* [3]. Karnezis *et al.* [11]
40 used a FE model to investigate the possibility of reducing the number of drawing passes.
Palengat *et al.* [12] underlined the importance of the properties of the interface (tube with
tools) on drawing limits. Several studies dealing with tools design have been achieved in
order to improve the process. Sheu *et al.* [13], Lee *et al.* [14] and Béland *et al.* [15] focused
on the die geometry while Kim *et al.* [16] had an interest for the mandrel one.

45 In this paper, a FE model is designed to precisely predict the final dimensions of the
tube. This axisymmetric steady-state model takes into account different issues including
tools geometry, tube elastoviscoplastic behaviour, tools elastic behaviour, contacts and
friction. Moreover, the numerical convergence is built to reach a 1-micron accuracy. In
consequence, this model can be used to analyse tube drawing process, and thus, permit a
50 better understanding.

This modelling was performed on Metafor [17, 18, 19], an in-house nonlinear finite ele-
ment code of the Department of Aerospace and Mechanical Engineering of the University
of Liège, Belgium.

This paper is organised as follows. A detailed model formulation is given in Section 2.
55 Then, Section 3 compares the numerical results with drawing experiments in order to vali-
date the model. Furthermore, a numerical analysis of the process is presented in Section 4.

Finally, Section 5 reports on the conclusions of this work.

2. Formulation of the finite element model

This section describes precisely the FE modelling. Tube sinking and mandrel drawing
 60 are treated together because of their many similarities. For the mandrel drawing, the
 reeling operation is not modelled. It implies that, at the end of the simulation, the tube
 remains clamped around the mandrel.

2.1. Geometry

By assumption, the tube and the tools are geometrically perfect. These elements are
 65 also supposed to be coaxial. Moreover, the geometry and the loading conditions have an
 axial symmetry. Thus, the process is axisymmetric and can be solved in 2D.

First, the tube is described by its outer and inner diameters (respectively D_{out} and
 D_{in}). Then, the die geometry includes various dimensions : the diameter D_{die} , the bear-
 70 ing length L_b , the entry die angle α . In the case of mandrel drawing, the inner tool is
 represented by its diameter D_m .

The geometry of the model is given in Figure 2. In practice, the beginning of the tube
 is inserted in the die before starting the drawing operation. The results of this area are
 not relevant. Besides, even if the die seems to be symmetric, the tool is not reversible. In
 fact, the die holder ensures that the die is used in the correct way.

FIGURE 2: Geometry of the model (mandrel drawing case)

75 2.2. Materials

In this model, the tube and the tools are both represented by deformable solids.

Element	Fe	Cr	Ni	Mo	Mn	Si
mass %	Balance	17-19	13-15	2.25-3	<2	<0.75
Element	Cu	N	C	P	S	
mass %	<0.5	<0.1	<0.03	<0.025	<0.01	

TABLE 1: Chemical composition of the 316LVM stainless steel (ASTM-F138 [20])

The tube is made of 316LVM stainless steel. This material is commonly used for biomedical applications because of its excellent resistance to various types of corrosion. Its chemical composition is given in Table 1.

80 Palengat *et al.* [12] observed an isotropic behaviour of this material. Then, Fréchart *et al.* [21] showed that :

- At ambient temperature (temperature of the process), nitrogen-alloyed austenitic stainless steels are strain-rate sensitive.
- And the viscoplastic model of Johnson-Cook is the most appropriate to describe

85 the behaviour of these materials at different strain rates.

The constitutive equation of this model [22] is :

$$\sigma_{eq} = (A + B\varepsilon_{eq}^n) \left(1 + C \ln \frac{\dot{\varepsilon}_{eq}}{\dot{\varepsilon}_{eq}^0} \right) \left(1 - \left(\frac{T - T_{ref}}{T_m - T_{ref}} \right)^m \right) \quad (1)$$

where σ_{eq} represents the flow stress, ε_{eq} the equivalent plastic strain, A the yield stress, B the pre-exponential factor, $\dot{\varepsilon}_{eq}$ the plastic strain rate, $\dot{\varepsilon}_{eq}^0$ the reference plastic strain rate, C the strain rate sensitivity coefficient, n the work-hardening coefficient, T the temperature of the material, T_m the melting temperature of the material, T_{ref} the reference temperature and m the thermal softening exponent. In other words, the first

90 the temperature of the material, T_m the melting temperature of the material, T_{ref} the reference temperature and m the thermal softening exponent. In other words, the first factor is related to the work hardening, the second one to the strain rate dependence and the last one to the thermal softening.

However, the thermal softening term can be neglected if the strain rate of the process

95 does not allow the material to be affected by the temperature rise [23]. On one side, the strain rate in cold drawing process can reach 40 s^{-1} . On the other, experimental measures showed that the tube temperature does not exceed 130°C [12], i.e. less than one tenth of the material melting point (1400°C). Thus, the thermal softening term can be safely neglected in (1). Finally, the von Mises yield criterion is used to model plasticity.

100 The mechanical properties and the Johnson-Cook parameters of 316LVM are respectively listed in Tables 2 and 3. A representation of the Johnson-Cook law is also given in Figure 3.

The die is made of tungsten carbide while the mandrel is made of steel. Both materials

Density	Young's Modulus	Poisson's ratio
7 900 kg.m ⁻³	192 GPa	0.29

TABLE 2: Mechanical properties of tube material

A	B	C	n	$\dot{\epsilon}_{eq}^0$
287 MPa	1265 MPa	0.021	0.664	0.03 s ⁻¹

TABLE 3: Johnson-Cook parameters of 316LVM stainless steel [24]

FIGURE 3: Representation of the Johnson-Cook law of 316LVM stainless steel for three plastic strain rates (with parameters of Table 3)

are considered as isotropic. During the process, no irreversible deformation is observed
105 in the tools so the behaviour is assumed to be perfectly elastic during the drawing. The
mechanical properties of tools materials are listed in Table 4.

2.3. Boundary conditions

Two boundary conditions are prescribed in this model (Figure 4).

The right extremity of the die is fixed along the drawing direction in order to model
110 the contact with the die holder. Then, a displacement condition is applied to the tube and
the mandrel, if it exists. This displacement is prescribed at constant speed. It corresponds

	Tungstene carbide	Steel
Density (kg.m^{-3})	15 000	7 900
Young's Modulus (GPa)	650	210
Poisson's ratio	0.3	0.3

TABLE 4: Mechanical properties of the tools materials

FIGURE 4: Boundary conditions of the model (mandrel drawing case)

to the steady speed of the drawing trolley.

2.4. Contact

Two contact pairs should be taken into account : tube/die and tube/mandrel.

115 In the industrial process, lubrication is used to reduce friction between each part. By assumption, it is homogeneous and constant.

Friction depends on several parameters : materials in contact, relative velocity, surface roughness, thickness of the oil film, normal pressure, etc. In this study, the contacts are described by a Coulomb friction model. Thus, two friction coefficients are defined :
 120 $\mu_{tube/die}$ and $\mu_{tube/mandrel}$. However, these coefficients are difficult to measure in practice. In consequence, an inverse analysis is used to identify them.

For each case, representative tests were performed experimentally and then, simulated with various friction coefficients. A nearly linear dependence was observed between the drawing force and the friction coefficient (Figure 5).

125 The coefficient, which permits us to match the simulated force with the measured one, was kept for the whole study. $\mu_{tube/die}$ was firstly identified thanks to a tube sinking test. This coefficient is assumed to be the same in both drawing methods. Then, a mandrel drawing test allowed us to determine $\mu_{tube/mandrel}$. The values of friction coefficients are listed in Table 5.

130 These values fit in the range of those of the literature about cold tube drawing. In fact, usual coefficients are included between 0.03 [3] and 0.2 [25].

$\mu_{tube/die}$	$\mu_{tube/mandrel}$
0.043	0.139

TABLE 5: Friction coefficients identified by inverse analysis

2.5. Mesh

The tube and the tools are meshed with 4-node-quadrangular elements using selective reduced integration (SRI) meaning that the pressure increment over an element is constant and computed at the centre of the element. While the deviatoric part of the stress tensor is evaluated at 4 Gauss points. Figure 6 shows a view of the initial mesh. In practice, only the upper half of the model (above the symmetric axis) is meshed and solved by the finite element method. Moreover, it could be mentioned that there is no contact between the tube and the tool on the right-hand part (corresponding to the tool area after the output plane in Figure 6). However, in order to simplify the mesh procedure and not to add another numerical parameter in the study (Section 2.6.2), the right-hand part of the tool is meshed in the same way as the left-hand part.

FIGURE 6: Initial mesh of the model (mandrel drawing case)

2.6. Analysis of numerical factors

This finite element model includes various numerical methods using different parameters. These methods are related to the contact algorithm, the mesh, the time integration and the required duration of the simulation to reach the steady state. Also, the parameters are chosen to assure a reliability of the model. In fact, all the following numbers result from a numerical study and ensure the best compromise between CPU time and the desired 1-micron accuracy (see Section 2.6.5).

2.6.1. Contact

Both contact pairs (tube/die and tube/mandrel) are numerically managed by the same methods using identical sets of parameters.

A penalty contact algorithm [18] is used. The penalty coefficient along the normal direction is equal to $10^7 \text{ MPa}\cdot\text{mm}^{-1}$. Along the tangential direction, the coefficient is defined as the normal one multiplied by the friction coefficient. This means that the geometrical error is identical along both directions when the surfaces slide over each other.

Finally, the contact is modelled as a node-to-surface contact using a single-pass method [19]. This implies that master and slave surfaces have to be assigned. On one side, the master surface corresponds to the more rigid one. Thus, in each case, the surface of the tool is considered as the master surface. On the other, the slave surface is assigned to the tube. Moreover, the depth, at which the detection occurs, is equal to half a tube thickness.

2.6.2. Mesh

165 The tube is meshed with 8 square elements in its thickness. This number is coherent with other studies. For instance, Palengat *et al.* [12] have used at least 8 elements in the thickness to study the forming limit.

In order to consume less CPU time, the tools are meshed with larger elements. In fact, the global size of the elements has been chosen to be ten times bigger in the die core than in the tube. This factor is equal to thirty for the mandrel. However, the mesh of the 170 tools is refined near the contact zones in order to avoid contact between segments with very different lengths. As previously, a size factor is defined : 0.5 for the die and 2 for the mandrel.

2.6.3. Time integration

175 A Chung-Hulbert scheme [26] is used for the time integration. This implicit dynamic integration scheme belongs to the generalized- α scheme family.

Then, the time increment is limited by a user-defined maximum value in order to ensure that the tube deformation is progressive and remains small during each increment. In this way, this value is defined so that a node covers the length of a tube element in 25 steps. 180 Although the resulting size of the time increment is rather small, it is significantly larger than the one expected with an explicit approach. Moreover, using the proposed implicit method, compared to an explicit one, prevents us from managing additional numerical parameters such as mass and load scaling factors and hourglass control.

Finally, the equilibrium tolerance within each increment is set to 10^{-4} to assure a 185 convergence without too much CPU time consumption.

2.6.4. Steady state

The duration of simulated process is set so that the whole tube is drawn and leave the die so that the springback is modelled.

Also, the modelled tube length should be sufficient to reach the steady-state conditions 190 far from tube ends during drawing. In this way, a minimum length of 20 mm should be considered.

2.6.5. Analysis method

All the previous parameters were set in order to guarantee the reliability of the model. The approach, that has been used, is explained in this paragraph.

195 A parameter is chosen : for instance, the penalty coefficient along the normal direction. This coefficient expresses, numerically, the stiffness of the contact. This means that greater it is, better the contact is represented.

Next, the value of this parameter is changed while the others are fixed. Table 6 gives an example of results.

Penalty coefficient (MPa.mm ⁻¹)	Drawing force (daN)	Outer diameter (mm)	Thickness (mm)	CPU Time
10 ⁴	854	7.0565	0.9839	54 min 30 s
10 ⁵	864	7.0207	0.9825	54 min 33 s
10 ⁶	866	7.0176	0.9822	55 min 21 s
10 ⁷	866	7.0172	0.9821	58 min 53 s
10 ⁸	867	7.0172	0.9821	1 h 43 min

TABLE 6: Analysis method to elect the best penalty coefficient used by the contact algorithm along the normal direction (tube sinking case)

200 According to the previous definition of this coefficient, the largest value (10⁸ MPa.mm⁻¹)
is taken as the reference. An error of 39.3 μm is observed on the outer diameter if the
coefficient is set to 10⁴ MPa.mm⁻¹. This error is bigger than the micron accuracy which
is expected. Thus, a coefficient of 10⁶ or 10⁷ MPa.mm⁻¹ allows us to verify this accuracy
while consuming less time than the reference. Finally, the value of 10⁷ MPa.mm⁻¹ was
205 chosen for the rest of the study.

3. Model validation with drawing experiments

Various drawing tests were performed on industrial benches in order to validate the model. Two of them are presented in this section.

3.1. Experiments

210 Test 1, performed for this paper, deals with tube sinking. A tube ($D_{out} = 9.88$ mm
and $D_{in} = 8.07$ mm) is pulled through a die of 7.01 mm of diameter. This corresponds
to an area reduction of 28%. Test 2, extracted from another work [4], concerns mandrel
drawing. The section area of a tube (8.16 mm x 7.05 mm) is reduced by 38% using a die
($D_{die} = 6.64$ mm) and a mandrel ($D_m = 5.80$ mm).

3.1.1. Measurements

215 The tube dimensions were precisely measured before and after the drawing operation.
The outer diameter was given by a laser measure (three points on two sections of the
tube). An Heidenhain touch probe was used to measure the thickness on eight points of
one tube section. The inner diameter was then deduced.

220 The dimensions of the die were measured thanks to a Mitutoyo coordinate measuring
machine.

As the outer diameter of the tube, the mandrel diameter was measured thanks to a laser. In the case of mandrel drawing, given the fact that the reeling operation is not simulated, the tube is clamped around the mandrel at the end of the process. In consequence, the measure of the tube outer diameter was done with the mandrel inside. Also, the thickness was deduced by assuming that the tube inner diameter is equal to the mandrel diameter. Tools measurements are listed in Table 7.

Test	Die			Mandrel
	D_{die} (mm)	L_b (mm)	α (deg)	D_m (mm)
1	7.012	2.010	14.859	-
2	6.64	2.4	22.0	5.80

TABLE 7: Tools dimensions

The tests were performed at ambient temperature (22 °C) and at constant speed (9.37 m.min⁻¹ for Test 1 and 11.4 m.min⁻¹ for Test 2).

3.1.2. Results

During the tests, the drawing force was measured by a load cell located between the die and the die holder. Figure 7 gives the evolution of the force during drawing.

Three stages can be discerned. At the beginning of the drawing (at $t = 0$ s), the force increases quickly. Then, a mechanical steady state is defined by a constant force. At $t = 12.3$ s, the tube gets out of the die (end of drawing) and the force becomes zero. Such evolution can be observed for all drawings.

The drawing tests results are summarised in Table 8.

Test	Initial tubes (mm)			Final tubes (mm)			Drawing force (daN)
	Outer \varnothing	Thickness	Inner \varnothing	Outer \varnothing	Thickness	Inner \varnothing	
1	9.875	0.901	8.073	7.019	0.959	5.101	867
	± 0.002	± 0.002		± 0.0005	± 0.003		± 11
2	8.16	0.555	7.05	6.6726	5.80	0.4363	739
	± 0.002	± 0.002		± 0.001			± 23

TABLE 8: Results of experimental drawing tests

3.2. Comparison with FE model

Both tests were simulated with the finite element model described in Section 2. This allowed us to calculate the drawing force, the outer diameter and the final thickness of the tubes.

FIGURE 7: Evolution of the experimental drawing force (Test 1)

In order to be consistent with experimental measurements, the numerical drawing force is calculated as the reaction force on the fixed side of the die (see Figure 4). The diameter and the thickness are calculated on a tube section which is not submissive to side effects.

Results of FE simulations are included in Table 9.

Test		Drawing force (daN)	Outer Diameter (mm)	Thickness (mm)
1	EXP	867	7.019	0.959
	FE	866	7.0172	0.9821
	Difference	1 0.1%	-0.0018 0.03%	+0.0231 2.41%
2	EXP	739	6.6726	0.4363
	FE	739	6.6689	0.4423
	Difference	0 <0.1%	-0.0037 0.06%	+0.006 1.38%

TABLE 9: Comparison between experimental (EXP) and FE results

As expected, the calculated drawing force is quite equal to the measured one. In fact, the friction coefficients, identified in Table 5, allow us to obtain this result.

In both tests, the outer diameter and the thickness are well predicted.

250 These simulations have used an Intel Core i7 3.20 GHz processor. The CPU statistics are listed in Table 10.

Test	Real drawing time (s)	CPU time	Number of steps
1	0.285	53 min 48 s	9994
2	0.208	4 h 26 min	18511

TABLE 10: CPU statistics

In conclusion, this comparison with drawing experiments shows that the presented model is able to predict the final dimensions of the tube with a good accuracy.

4. Numerical analysis of the process

255 The validated model can be used to give a better understanding of cold tube drawing process. In this purpose, five studies are presented in this section.

4.1. Influence of the die angle on the drawing force

260 The required pulling force to draw a tube is a critical value in the design of the industrial process because it calibrates the bench capacity. Thus, it is interesting to know the influence of process parameters on the force.

In particular, the entry die angle is strongly linked to it. In this way, a tube sinking simulation was repeated with various angle values (from 10° to 30° by step of 1°). The other parameters are those of Test 1 (see Table 7). The drawing force variations are shown in Figure 8. Also, the equivalent plastic strain is given in Figure 9 for three values of the die angle.

265 Béland *et al.* [15] revealed that an optimum value of the die angle minimises the drawing force. This result can be observed here for $\alpha = 17^\circ$.

When the die angle deviates from the optimum value, the force increases. However, a dissymmetry is observed because the increase, on either side of the optimum value, does not have the same origin. When the die angle is below the optimum value, the friction predominates over the deformation. If the angle decreases, the friction between the tube and the die increases and so the force increases. When the die angle is above the optimum value, the deformation predominates over the friction. If the angle increases, the tube must deform more in order to keep a constant material flow. In consequence, a greater force is needed.

275 Finally, Figure 9 shows that the equivalent plastic strain of the tube increases with the die angle. Furthermore, the model predicts that, in the presented cases of tube sinking,

FIGURE 8: Drawing force as a function of the die angle (tube sinking case)

no contact occurs between the tube and the die, along the bearing length. Due to a scale effect, this observation is more visible in Figure 9(c).

280 *4.2. Influence of the initial relative thickness on the geometry of the tube*

Various tube thicknesses could be drawn through a given die. In consequence, a dimensionless quantity is used to compare the different kinds of drawings. The relative thickness of the tube is defined as the ratio between the thickness and the outer radius.

285 During the drawing, the tube deformation is directly influenced by its initial relative thickness. Figure 10 shows the variation rate of thickness as a function of the relative thickness, for tube sinking. This graph is obtained by repeating the simulation of Test 1 with various values of the initial inner diameter of the tube in order to reach a wide range of relative thicknesses.

290 When the initial relative thickness increases, the variation rate of the thickness decreases. Also, in the presented case, the thickness is not modified by the drawing operation if the dimensionless quantity is equal to 40%. So, two behaviours can be distinguished. If the relative thickness is below 40%, the variation rate is positive. In other words, the tube gets thicker after drawing. If the relative thickness is above 40%, the variation rate is negative, and so, due to the drawing, the tube thickness decreases. This behaviour is 295 commonly observed in practice in the industry.

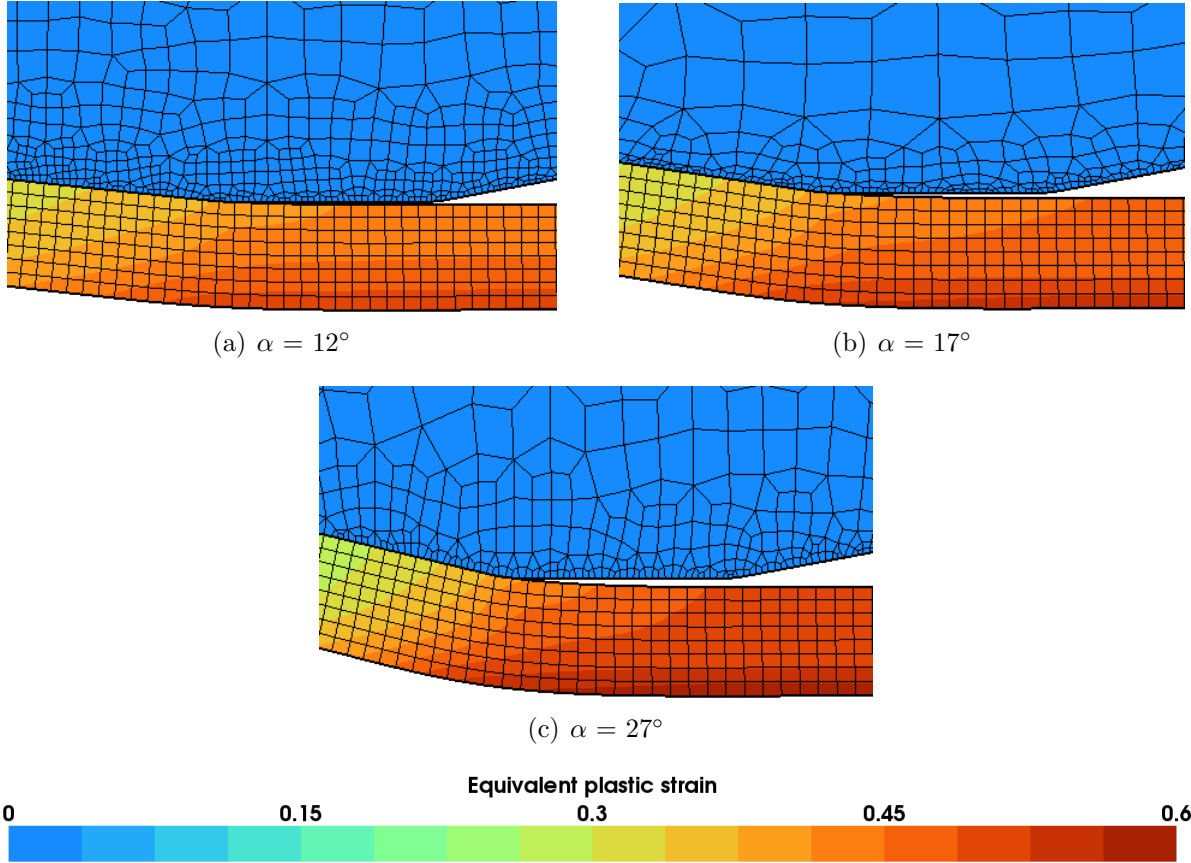

FIGURE 9: Equivalent plastic strain of the tube for three values of die angle, at the steady state (tube sinking case)

4.3. Influence of the initial relative thickness on the elongation

As the drawing process implies a diameter reduction, the tube is stretched. In this study, the influence of the initial relative thickness on the elongation is studied for tube sinking. A representation of the elongation evolution is given in Figure 11. This graph is actually obtained with the same simulations as in Section 4.2.

The elongation increases with the relative thickness in a quite linear way. In fact, the greater the relative thickness, the greater the area reduction. Thus, due to volume conservation, the tube is more stretched. This figure also reveals that the outer and inner surfaces have the same elongation even if the outer is constrained by the die and the inner is free to deform.

FIGURE 10: Influence of the relative thickness on the final tube thickness (tube sinking case)

FIGURE 11: Elongation as a function of the initial relative thickness of the tube (tube sinking case)

4.4. Distribution of residual stresses in the tube thickness

The tube is subjected to strain hardening during cold tube drawing. An analysis of the residual stresses through the thickness allows us to understand the tube state at the end of the drawing. Figure 12 gives an example for tube sinking (Test 1).

FIGURE 12: Distribution of residual stresses in the thickness for tube sinking

310 The evolution of the von Mises stress through the thickness reveals that the tube is more constrained on its inner surface than on its outer one. Then, shear and radial stresses are not significant. Moreover, the circumferential stress is negative in the inner part of the tube and positive in the outer one. Finally, as far as the longitudinal stress is concerned, the tube is in compression on its inner surface and in traction on its outer one.

315 4.5. Prediction of the reeling operation

In the case of mandrel drawing, the tube is clamped around the mandrel at the end of the process. A reeling operation is needed to remove the mandrel from the tube. It consists in relaxing the tube stresses thanks to a roller system.

320 In practical, this operation is difficult to perform on some tubes. Even if the reeling operation is not simulated with this model, a qualitative study is proposed in this section, to predict the difficulty of the reeling operation of two tubes.

Experiments have showed that the reeling operation of Tube B is more difficult than the one of Tube A. The characteristics of the drawings preceding the reeling operation are presented in Table 11.

Tube	Die			Mandrel	Speed
	D_{die} (<i>mm</i>)	L_b (<i>mm</i>)	α (<i>deg</i>)	D_m (<i>mm</i>)	(<i>m.min</i> ⁻¹)
A	7.48	0.9	22.7	6.50	11.4
B	8.13	0.3	33.0	7.00	11.4

Tube	Initial tubes (mm)			Final tubes (mm)		
	Outer \varnothing	Thickness	Inner \varnothing	Outer \varnothing	Thickness	Inner \varnothing
A	9.05	0.64	7.77	7.52	0.51	6.50
B	10.50	0.75	9.00	8.16	0.58	7.00

TABLE 11: Mandrel drawings of Tubes A and B before the reeling operation - extracted from [4]

325 Considering that the clamping on the mandrel is due to the residual radial stress, the idea is to compare the distribution of this stress through the final section after drawing for both tubes. Figure 13 represents the repartition of radial stress in the thickness for Tubes A and B.

330 For both tubes, the radial stress is negative, except on the outer skin. This compression is coherent with the tube clamping observed in practice. It can also be observed that the compression is more important in Tube B than in Tube A (by a factor of 1.55 on the inner skin). In consequence, a greater relaxation is necessary for Tube B. Thus the simulation confirms that removing the mandrel from Tube A by a reeling operation is easier than from Tube B.

335 Of course, the results of this qualitative study should be ideally confirmed by a full simulation of the removal process. The simulation of this complete post-operation will be investigated in future models.

5. Conclusions

340 A finite element model of cold tube drawing has been presented in this paper. Also, the numerical parameters have been chosen to assure the reliability of the model.

Then, drawing experiments have been achieved and compared to simulations in order to validate the model. This showed that the final dimensions of the tube can be predicted by the model with a good accuracy.

FIGURE 13: Repartition of radial stress before reeling operation

Furthermore, a complete analysis of the process has been presented. It has been shown
 345 that the die angle has an influence on the drawing force. Also, the relative thickness has
 an impact on the mechanical behaviour of the tube during the drawing operation. In fact,
 it can become thicker or thinner depending on the relative thickness is below or above
 a transition value (which is 40% in the presented case). Moreover, the tube elongation,
 identical on inner and outer surfaces, increases with the relative thickness. Finally, an
 350 analysis of the residual stresses allowed to understand the tube state at the end of the
 drawing. In particular, it can qualify the difficulty of the reeling operation in the case of
 a mandrel drawing.

As part of the optimisation of the process parameters, this first work gives us promising
 results. Other studies will be considered in future works : thermal effects, anisotropy of
 355 the tube material and chaining several successive drawing operations.
